———————— Abstract ————————

What accounts for income per capita and total factor productivity (TFP) differences across countries? We study resource misallocation across heterogeneous production units in a general equilibrium model where establishment productivity and size are affected by policy distortions. We solve the model in closed form and show that the effect of policy distortions hinges crucially on the size distribution of establishments approximately satisfying Zipf's law, an empirical phenomenon that can be interpreted to imply that misallocation is low or that the establishments' lifespan is long, or both. More distorted economies feature higher establishment lifespan which amplifies the negative effect of distortions on productivity and establishment growth. Policy distortions substantially reduce aggregate TFP, an effect that is 2.8-fold larger than in the model with unrestricted size distribution and 6.9-fold larger with perfectly correlated distortions.

Keywords: distortions, misallocation, investment, productivity, Zipf's law.

# 1   Introduction

A crucial question in economic growth and development is why some countries are rich and others poor. A consensus has emerged in the literature whereby the large differences in income per capita across countries are mostly accounted for by differences in labor productivity and in particular total factor productivity (TFP) (Klenow and Rodriguez-Clare, 1997; Prescott, 1998; Hall and Jones, 1999). Hence, a key question is: what accounts for differences in TFP across countries? An important channel that has been emphasized is the (mis)allocation of factors across heterogeneous production units.[1] We study misallocation in a model where establishment-level productivity is determined endogenously by the investment decisions of firms. In particular, we restrict to economies with constant size distribution of establishments, which approximate Zipf's law, and show that policy distortions substantially reduce aggregate productivity, by orders of magnitude compared to similar frameworks when the size distribution is unrestricted.

A recent branch of the literature has emphasized the dynamic implications of misallocation by considering variants of the growth model with establishment-level productivity dynamics.[2] We build on this literature by developing a general equilibrium model of establishment productivity where the distributions of establishment productivity and size are characterized in closed form as a function of the economic environment which is affected by policy distortions.

A key insight of our work arises from exploiting two well-known properties of distorted economies, that establishment size is proportional to distortions and productivity (Restuccia and Rogerson, 2008) and that the distribution of (relative) sizes across establishments is fairly similar across countries and approximates Zipf's law (Axtell, 2001; Gabaix, 2009; Luttmer, 2007; Hopenhayn, 2014a). This implies that variations in policy distortions across economies are mostly reflected in

[2]Some of the early contributions on the endogenous productivity distribution include Restuccia (2013b), Bello et al. (2011), Acemoglu et al. (2018), Ranasinghe (2014), Bhattacharya et al. (2013), Gabler and Poschke (2013), Rubini (2014), Hsieh and Klenow (2014), Bento and Restuccia (2017), Guner et al. (2018), Peters (2015), Buera and Fattal Jaef (2018), among others. See also Restuccia and Rogerson (2017) for a discussion of this literature.

differences in the productivity distribution. This effect is quantitatively important as distortions in our framework reduce aggregate TFP by 57% compared with only 21% in the same economy that does not restrict the size distribution of establishments (a 2.7-fold larger impact) and only 9% in an economy perfectly correlated distortions commonly assumed in the literature (a 6.3-fold larger impact). Moreover, our analytical solution of the distribution of productivity and how it is affected by distortions can potentially be useful in empirical applications of dynamic misallocation across countries using panel micro data, an essential issue in the misallocation literature (Restuccia and Rogerson, 2017).

We develop a general equilibrium framework with heterogeneous production units that builds on Hopenhayn (1992) and Restuccia and Rogerson (2008). The framework is a standard neoclassical growth model with production heterogeneity extended to incorporate the dynamic effect of distortions on productivity investment and hence the distribution of establishment-level productivity. The key elements of the model are on the production side. In each period, there is a single good produced in establishments. Establishments are heterogeneous with respect to total factor productivity and have access to a decreasing returns to scale technology with capital and labor as inputs. Establishments are subject to an exogenous exit rate but differently from the standard framework, the distribution of establishment-level productivity is not exogenous, rather it is determined by establishment's decisions. In other words, the productivity of establishments is determined endogenously in the model by the properties of the economic environment such as policy distortions.

Following the literature, the economy faces policy distortions which, for simplicity, take the form of output taxes on individual producers. That is, each producer faces an idiosyncratic tax and it is the properties of policy distortions that generate misallocation in the model. Revenues collected from these taxes are rebated back to the households as a lump-sum transfer. We emphasize that the output distortions we consider are abstract representations, a catch-all for the myriad of implicit and explicit distortions faced by individual producers. While the literature has made substantial progress in identifying the specific policies and institutions that create misallocation, as discussed in Restuccia and Rogerson (2017), the emphasis in our paper is on effect of distortions on the

productivity distribution in the economy. As a result, our paper represents a general assessment of the broader consequences of misallocation.

We provide an analytical solution of this model in continuous time. In particular, we solve in closed form for the stationary distributions of establishment sizes and productivities which are endogenous objects that may vary across economies. We show that the equilibrium productivity distributions are Double Pareto distributions with tail index that depends on policy distortions and on the response of incumbent establishments to distortions when selecting the growth rate of productivity. This allows us to characterize the behavior of aggregate output and TFP across distortionary policy configurations as well as the size and productivity growth rate of establishments, the inequality of the distributions of size and establishment-level productivity, among other statistics of interest.

To explore the quantitative properties of the model relative to the existing literature, we calibrate the model and provide a set of relevant quantitative experiments. We consider a benchmark economy with distortions that is calibrated to data for the United States. The key discipline in our calibration is that the size distribution of establishments is restricted to approximately follow Zipf's law (Axtell, 2001). We then perform quantitative analysis by exploring the implications of increasing distortions for aggregate output and TFP under a variety of configurations.

Our main result is that in economies with weak correlated distortions, Zipf's law is key for policy distortions to reduce the average size of establishments, establishment entry productivity, and establishment productivity growth; effects which are broadly consistent with the evidence on average establishment size (Bento and Restuccia, 2017), with evidence that in more distorted economies the productivity and employment growth of establishments are lower (Hsieh and Klenow, 2014), and with evidence that when distortions are removed, the growth rate of establishments increases (Pavcnik, 2002; Bustos, 2011).

Our paper is related to a large literature on misallocation and productivity discussed earlier. The literature has emphasized various separate channels such as life-cycle investment of plants, human capital accumulation of managers, experimentation, step-by-step innovation, selection, among many

4

others; and different contexts such as trade and labor policies, financial frictions, and specific sectors. We complement this literature by developing a general model of establishment growth featuring a distribution of establishment productivity that can be characterized in closed form. More importantly, our theoretical characterization can be useful in developing methods to estimate the role of dynamic misallocation using panel data of firms, and hence we hope our analysis can facilitate more empirical applications.

Two closely related papers to ours are Hsieh and Klenow (2014) and Bento and Restuccia (2017). Hsieh and Klenow (2014) consider the model of establishment innovation in Atkeson and Burstein (2010) to emphasize the life-cycle growth of establishments and its response to distortions, whereas Bento and Restuccia (2017) emphasize both entry productivity and life-cycle growth. We emphasize two key distinctions with our work. First, in these papers entering establishments draw their productivity from an exogenous and constant distribution across countries, whereas the entire productivity distribution is a key equilibrium object in our framework that responds to policy distortions. Second, we differ in the tools used to characterize the economy, in particular, we solve analytically for the entire distribution of productivity using continuous time and Brownian motion processes. These tools are increasingly popular in the growth literature allowing both a tighter theoretical characterization and more efficient computation (e.g., Lucas and Moll, 2014; Benhabib et al., 2014; Buera and Oberfield, 2014). More closely linked, these tools were prominently used in the seminal work of Luttmer (2007) to study the size distribution of establishments in the United States (see also Da-Rocha and Pujolas, 2011; Fattal, 2014; Gourio and Roys, 2014; Da-Rocha et al., 2019).

The paper proceeds as follows. In the next section, we present the details of the model and section 3 characterizes the equilibrium solution. In section 4, we characterize aggregate output and TFP and provide a closed-form solution of the model. Section 5 provides a quantitative assessment of the impact of policy distortions on aggregate output, TFP, and other relevant statistics. We conclude in Section 6.

5

# 2 Economic Environment

We consider a standard version of the neoclassical growth model with producer heterogeneity as in Restuccia and Rogerson (2008). We extend this framework to allow establishments to invest in their productivity. As as a result, with on-going entry and exit of establishments, the framework generates an invariant distribution of productivity across establishments associated with the economic environment that may differ across countries. Time is continuous and the horizon is infinite. Establishments have access to a decreasing return to scale technology, pay a one-time fixed cost of entry, and exit at an exogenous rate. Establishments hire labor and rent capital services in competitive markets. New entrants enter with a level of productivity which is endogenous. We focus on a stationary equilibrium of this model and study the effects of idiosyncratic policy distortions on the allocation of factors across establishments. In what follows, we provide more details of the economic environment.

## 2.1 Baseline Model

There is an infinity-lived representative household with preferences over consumption goods described by the utility function,

$$\max \int_0^{+\infty} e^{-\varrho t} u(c) dt,$$

where $c$ is consumption and $\varrho$ is the discount rate. The household is endowed with one unit of productive time at each instant and $k_0 > 0$ units of the capital stock at date 0.

The unit of production in the economy is the establishment. Each establishment is described by a production function $f(z, k, n)$ that combines establishment productivity $z$, capital services $k$, and labor services $n$ to produce output. The function $f$ is assumed to exhibit decreasing returns to scale in capital and labor jointly and to satisfy the usual Inada conditions. The production function is

given by:

$$y = z^{\theta(1-\alpha-\gamma)}k^{\alpha}n^{\gamma}, \quad \alpha, \gamma \in (0,1), \quad 0 < \gamma + \alpha < 1, \quad \theta > 1, \tag{1}$$

where establishment productivity $z$ is stochastic but establishments can invest in upgrading their productivity at a cost and $\theta$ is a scaling parameter for establishment TFP. Note that establishment TFP is $z^{\theta(1-\alpha-\gamma)}$ and hence $\theta$ influences the units in which establishment productivity $z$ is measured. Scaling productivity by $\theta$ is convenient for algebraic manipulations of the model as this parameter also represents the curvature in the cost function of establishment productivity growth, but other than the economics of productivity investment, this scaling of productivity is innocuous for the analysis. Establishments also face an exogenous probability of exit $\lambda$.

New establishments can also be created. Entrants must pay an entry cost $c_e$ measured in units of output and as in the literature the expected value of entry satisfies the zero profit condition in equilibrium. Feasibility in the model requires:

$$C + I + Q = Y - E,$$

where $C$ is aggregate consumption, $I$ is aggregate investment in physical capital, $Q$ is aggregate cost of investing in establishment productivity, $E$ is the aggregate cost of entry, and $Y$ is aggregate output.

## 2.2 Policy Distortions

We introduce policies that create idiosyncratic distortions to establishment-level decisions as in Restuccia and Rogerson (2008). We model these distortions as idiosyncratic output taxes but none of our results are critically dependent on the particular source of distortions. While the policies we consider are hypothetical, there is a large empirical literature documenting the extent of idiosyncratic distortions across countries and our framework allows for a simple mapping between

distortions and empirical observations (Hsieh and Klenow, 2009; Bartelsman et al., 2013; Restuccia and Rogerson, 2017).

In our framework, distortions not only affect the allocation of resources across existing production units, but also the growth rate of establishment productivity, thereby affecting the distribution of productive units in the economy. Specifically, we assume that each establishment faces its own policy distortion (idiosyncratic distortions) reflected as an output tax rate $\tau_y$. In what follows, for convenience we rewrite distortions as $\tau = (1 - \tau_y)^{\frac{1}{\theta(1-\alpha-\gamma)}}$. Note that this transformation implies that an establishment with no distortions $\tau_y = 0$ faces $\tau = 1$, whereas a positive output tax $\tau_y > 0$ implies $\tau < 1$ and an output subsidy $\tau_y < 0$ implies $\tau > 1$.

In order to generate dispersion in distortions across productive units, we assume that $\tau$ follows a standard stochastic process, a Geometric Brownian motion,

$$dz = \mu_\tau \tau dt + \sigma_\tau \tau dw_\tau,$$

where $\mu_\tau$ is the drift, $\sigma_\tau$ is the standard deviation and $dw_\tau$ is the standard Wiener process of the Brownian motion. In this specification $\sigma_\tau$ controls the dispersion of distortions across producers and hence the dispersion in marginal revenue products.

Establishment's productivity $z$ follows a Geometric Brownian motion and establishments can invest in upgrading their productivity by choosing the drift of the Brownian motion $\mu_z$, establishment productivity follows:

$$dz = \mu_z z dt + \sigma_z z dw_z,$$

where $\sigma_z$ is the standard deviation and $dw_z$ is the standard Wiener process of the Brownian motion. We assume that the output tax and productivity can be correlated, that is $E(dw_\tau, dw_z) = \rho \in (-1, 0]$. Note that a negative value of $\rho$, corresponds to the notion of correlated distortions in Restuccia and Rogerson (2008), whereby distortions impact more heavily on more productive establishments.

At the time of entry, the entry distortion $\tau_e$ is known and establishments enter with a productivity $z_e$ that is determined in equilibrium and implies a value of entrants that satisfies the zero profit condition. In this economy, the relevant information for establishment's decisions is the joint distribution over productivity and distortions. We denote this joint distribution by $g(z, \tau)$.

A given distribution of establishment-level distortion and productivity may not lead to a balanced budget for the government. As a result, we assume that budget balance is achieved by either lump-sum taxation or redistribution to the representative household, denoting the lump-sum tax by $T$.

# 3    Equilibrium

We focus on a stationary equilibrium of this economy. The stationary equilibrium is characterized by an invariant distribution of establishments $g(z, \tau)$ over productivity $z$ and distortion $\tau$, a constant entry productivity $z_e$, and constant allocation functions. In the stationary equilibrium, the rental price for labor and capital services are also constant and we denote them by $w$ and $r$. Before defining the stationary equilibrium formally, it is useful to consider the decision problems faced by incumbents, entrants, and consumers. We describe these problems in turn.

## 3.1    Incumbent establishments

Incumbent establishments maximize the present value of profits by making static and dynamic decisions. The static problem is to choose the amount of capital and labor services, whereas the dynamic problem involves solving for the establishment productivity drift. We now describe these problems in detail.

**Static problem**    At any instant of time an establishment chooses how much capital to rent $k$ and how much labor to hire $n$. These decisions are static and depend on the establishment's productivity

$z$, the establishment's distortion $\tau$, the rental rate of capital $r$, and the wage rate $w$. Formally, the instant profit function $\pi(z,\tau)$ is defined by:

$$\pi(z,\tau) = \max_{k,n}(\tau z)^{\theta(1-\alpha-\gamma)}k^\alpha n^\gamma - wn - rk, \tag{2}$$

from which we obtain the optimal demand for labor and capital:

$$n(z,\tau) = \left[\left(\frac{\alpha}{r}\right)^\alpha \left(\frac{\gamma}{w}\right)^{1-\alpha}\right]^{\frac{1}{1-\alpha-\gamma}} z^\theta \tau^\theta, \tag{3}$$

$$k(z,\tau) = \left[\left(\frac{\alpha}{r}\right)^{1-\gamma} \left(\frac{\gamma}{w}\right)^\gamma\right]^{\frac{1}{1-\alpha-\gamma}} z^\theta \tau^\theta. \tag{4}$$

For future reference, we redefine instant profits as a function of the optimal demand for factors:

$$\pi(z,\tau) = m(w,r)z^\theta \tau^\theta, \tag{5}$$

where $m(w,r) = (1-\alpha-\gamma)\left[\left(\frac{\alpha}{r}\right)^\alpha \left(\frac{\gamma}{w}\right)^\gamma\right]^{\frac{1}{1-\alpha-\gamma}}$ is a constant across establishments that depends on equilibrium prices. Note that since factor demands are linear in $(z\tau)^\theta$, we find it convenient to define size $s$ as $s \equiv (z\tau)^\theta$ so that factor demands are proportional to size $s$. A key insight of the misallocation literature is that the relationship between size and productivity is fundamentally affected by distortions. In this setting, distortions put a wedge between factor demands (and revenue) and physical output. Unlike factor demands (as well as revenue and profits), establishment output $y = z^{\theta(1-\alpha-\gamma)}k^\alpha n^\gamma$ is not a linear function of size. We explicitly derive the relationship between output, distortions, and productivity below.

**Dynamic problem**  Incumbent establishments choose the drift of their productivity $\mu_z$. The cost of investing in productivity is expressed in units of output, described by a cost function $q(\mu_z)$ that is increasing and convex in the productivity drift, specifically we assume $q(\mu_z) = \left(\frac{c_\mu \mu_z^\theta}{\theta}\right)\frac{z^\theta \tau^\theta}{\bar{s}}$, where $\theta$ controls the convexity of the cost function and $c_\mu$ is a common scale parameter. The cost

function is proportional to (relative) establishment size by a factor $\left(\frac{c_\mu \mu_z^\theta}{\theta}\right)$ which implies that all establishments choose the same productivity drift. This assumption regarding the cost function is common in the innovation literature where costs are proportional to (relative) revenue (Atkeson and Burstein, 2010; Buera and Fattal Jaef, 2018), and guarantees that Gibrat's law holds, implying that the growth rate of an individual establishment does not depend on the the establishment's intrinsic characteristics. In our context, revenue is not only proportional to productivity but also distortions. The optimal decision of productivity improvement is characterized by maximizing the present value of profits subject to the Brownian motion governing the evolution of productivity and the Brownian motion governing the evolution of distortions. Formally, incumbent establishments solve the following dynamic problem:

$$W(z,\tau) = \max_{\mu_z} \left\{ m(w,r)z^\theta \tau^\theta - q(\mu_z) + \frac{1}{1+(\lambda+R)dt} E_{z,\tau} W(z+dz, \tau+d\tau) \right\},$$

(6)

$$s.t. \quad dz = \mu_z z dt + \sigma_z z dw_z,$$
$$d\tau = \mu_\tau \tau dt + \sigma_\tau \tau dw_\tau,$$

where $\lambda$ is the exogenous exit probability of establishments and $R$ is the stationary equilibrium real interest rate. Next, we define the Hamilton-Jacobi-Bellman of the stationary solution,

$$(\lambda + R)W(z,\tau) = \max_{\mu_z} \left\{ m(w,r)z^\theta \tau^\theta - \frac{c_\mu}{\bar{s}} \frac{\mu_z^\theta}{\theta} z^\theta \tau^\theta \right.$$
$$\left. + \mu_z z W_z' + \frac{\sigma_z^2}{2} z^2 W_{zz}'' + \mu_\tau \tau W_\tau' + \frac{\sigma_\tau^2}{2} \tau^2 W_{\tau\tau}'' + \sigma_z \sigma_\tau \rho z \tau W_{z\tau}'' \right\}.$$

(7)

In the following Lemma 1 we characterize formally the endogenous productivity drift.

**Lemma 1.** *Given distortion $\tau$, productivity $z$, and operating profits $m(w,r)$, the value function that solves the establishment dynamic problem is given by $W(z,\tau) = A(w,r)\tau^\theta z^\theta$ where*

$$A(w,r) = \frac{m(w,r)}{\lambda + R + \mu_z - \left[\theta(\mu_\tau + \mu_z) + \theta^2 \sigma_z \sigma_\tau \rho + \frac{\theta(\theta-1)}{2}(\sigma_z^2 + \sigma_\tau^2)\right]},$$

11

*and the productivity drift*

$$\mu_z = \left[ \frac{\theta A(w,r)\bar{s}}{c_\mu} \right]^{\frac{1}{\theta - 1}}.$$

**Proof** See Appendix A.1.

The implication of Lemma 1 is that the growth rate of productivity of individual establishments is constant and common across establishments, that is, it does not depend on the intrinsic characteristics of the establishment such as productivity $z$ or distortion $\tau$, as a result Gibrat's law holds. We recognize that there is some debate as to whether Gibrat's law holds empirically, however, we note that this implication of the model implies a more muted negative effect of distortions on output, making our quantitative results conservative in this context. Atkeson and Burstein (2010) develop a model of firm-level innovation with the same property, whereas in Bhattacharya et al. (2013) and Hsieh and Klenow (2014) it holds for undistorted economies but not for distorted economies. While Lemma 1 implies that the endogenous productivity drift is constant across establishments, the drift can differ across economies with different policy distortions when distortions affect equilibrium wages, and this is a key element in our quantitative analysis.

Employment, which is proportional to size $n \propto s = (z\tau)^\theta$, also follows Gibrat's law, and the resulting Brownian motion of size implies the following drift:

$$\mu_s = \theta \left( \mu_z + \mu_\tau + \theta \sigma_z \sigma_\tau \rho \right) + \theta(\theta - 1)(\sigma_z^2 + \sigma_\tau^2)/2. \tag{8}$$

In this environment, policy distortions affect productivity growth and employment growth differently. Employment is impacted by distortions directly through the dispersion of distortions $\sigma_\tau$ and its correlation with productivity $\rho$, and indirectly through changes in productivity growth $\mu_z(w,r)$. Not only size is not the same as productivity in distorted economies in this framework, but also growth in size is not the same as growth in productivity.

## 3.2   Entering establishments

Potential entering establishments face an entry cost $c_e$ in units of output and make their entry decision knowing the entry distortion $\tau_e$. For tractability, we assume that entrants start with the same level of productivity, denoted by $z_e$. The initial level of productivity is such that the value of entering establishments satisfies the zero profit condition:

$$W_e = A(w,r)(\tau_e z_e)^\theta - c_e = A(w,r)s_e - c_e = 0. \tag{9}$$

Note that such a value of productivity $z_e$ exists and is unique which follows from the fact that the value of entry $W_e$ inherits the properties of the value of incumbent establishments which is increasing in productivity $z_e$. In addition, in the special case where the model is deterministic, the value of entry is the same as in Restuccia and Rogerson (2008), which is the discounted value of establishments' profit.

## 3.3   Stationary distribution of establishments

Given the optimal decisions of incumbents and entering establishments, we are now ready to characterize the stationary distribution $g(z, \tau)$ over productivity $z$ and distortion $\tau$. The first step to characterize this distribution is to rewrite the Brownian motions of productivity $z$ and distortion $\tau$ as a function of size $s$. In order to characterize the stationary distribution over size, it is useful to rewrite the model in logarithms. Let $x$ denote the logarithm of relative size, that is $x = \log(s/s_e)$, where $s_e = (\tau_e z_e)^\theta$ is the size in which establishments enter. Now we can rewrite the Geometric Brownian motion of $x$ as

$$dx = \mu_x dt + \sigma_x dw_x,$$

where

$$\mu_x = \theta(\mu_z + \mu_\tau) + \frac{\theta(\theta-1)}{2}(\sigma_z^2 + \sigma_\tau^2) - \frac{\theta^2}{2}(\sigma_z^2 + \sigma_z^2),$$

and

$$\sigma_x^2 = \theta^2 \left( \sigma_z^2 + \sigma_\tau^2 + 2\sigma_z\sigma_\tau\rho \right). \tag{10}$$

We use the Kolmogorov-Fokker-Planck (KFP) equation to characterize the stationary distribution of $x$:

$$\frac{\partial f(x,t)}{\partial t} = -\mu_x \frac{\partial f(x,t)}{\partial x} + \frac{\sigma_x^2}{2} \frac{\partial^2 f(x,t)}{\partial x^2} - \lambda f(x,t) + b(0,t), \tag{11}$$

where $\lambda$ is the exogenous exit rate of establishments, $b(0,t)$ is the measure of establishments that enter at time $t$ and have size $0$, after the normalization. The solution of this problem is discussed in Gabaix (2009). We are interested in solving for the steady state where $f(x,t) = f(x)$ and $b(0,t) = b(0)$. Therefore, we can rewrite the KFP equation (11) as:

$$f'(x) = -\mu_x f'(x) + \frac{\sigma_x^2}{2} f''(x) - \lambda f(x) + b\delta(x - 0) = 0, \tag{12}$$

and we assume four boundary conditions:

$$\lim_{x\to-\infty} f(x) = 0, \qquad \lim_{x\to+\infty} f(x) = 0, \tag{13}$$

$$\lim_{x\to-\infty} f'(x) = 0, \qquad \lim_{x\to+\infty} f'(x) = 0, \tag{14}$$

and that $f(\cdot)$ is a *p.d.f*, i.e. $f(x) \geq 0$ and $\int_{-\infty}^{+\infty} f(x)dx = 1$. The first two boundary conditions (13) guarantee that the stationary distribution is bounded, whereas the next two boundary conditions (14) imply that $b$ is equal to $\lambda$, that is, the stationary equilibrium entry rate is equal to the exogenous exit rate.[3] We can now characterize the stationary (log) size distribution, which is a double Pareto. Formally, Lemma 2 characterizes the stationary distribution.

---

[3]Integrating (12) we obtain:

$$\int_\infty^{+\infty} f'(x)dx = \left( -\mu_x f(x) + \frac{\sigma_x^2}{2} f'(x) \right)\Big|_{-\infty}^{+\infty} - \lambda \int_{-\infty}^{+\infty} f(x)dx + \int_{-\infty}^{+\infty} b\delta(x - 0)dx = 0,$$

and applying the boundary conditions and using the Dirac delta function, $\int_{-\infty}^{+\infty} \delta(x - 0)dx = 1$, results in $b = \lambda$.

**Lemma 2.** *Given wages $w$, rental rate of capital $r$, and a policy $(\tau_e, \mu_\tau, \sigma_\tau, \rho)$ the stationary size distribution is a double Pareto:*

$$
g(s) = \begin{cases} C\left(\dfrac{s}{s_e}\right)^{-(\xi_- + 1)} & \text{for} \quad s < s_e. \\[3mm] C\left(\dfrac{s}{s_e}\right)^{-(\xi_+ + 1)} & \text{for} \quad s \geq s_e. \end{cases} \tag{15}
$$

*where the tail index $\xi_+$ is the positive root and the tail index $\xi_-$ is the negative root that solves the characteristic equation*

$$
\frac{\sigma_x^2}{2}\xi^2 + \left(\mu_s - \frac{\sigma_x^2}{2}\right)\xi - \lambda = 0 \tag{16}
$$

*and $C = \dfrac{-\xi_- \xi_+}{s_e(\xi_+ - \xi_-)}$. Moreover, average establishments size $\bar{s}$ is given by:*

$$
\bar{s} = \left(\frac{\lambda}{\lambda - \mu_s}\right) s_e.
$$

**Proof** See Appendix A.2.

We leave the poof of Lemma 2 to the Appendix. Lemma 2 characterizes the endogenous distribution as a function of establishments' size drift $\mu_s$ and entry size $s_e$, which in turn are affected by distortions.

## 3.4 Household's problem

The household problem essentially help us pin down the stationary real interest rate $R$. As such, the process for capital accumulation in this model follows the standard neoclassical growth model. The stand-in household seeks to maximize lifetime utility subject to the law of motion of wealth given by:

$$
(RK + w + T + \Pi - bc_e - c)\, dt,
$$

where $w$ is the wage rate, $R$ is the interest rate which in equilibrium is the rental price of capital minus capital depreciation ($R = r - \delta_k$), $T$ is the lump-sum tax levied by the government, $\Pi$ is the total profit from the operation of all establishments, $bc_e$ is the total entry cost of establishments and $c$ is consumption.

We assume that households have log utility, $u(c) = \log(c)$. The solution of this problem is standard and implies that $R = \varrho$. In the stationary equilibrium, aggregate consumption $C$ and physical capital $K$ are constants.

## 3.5   Stationary equilibrium

**Definition** Given a policy $\{\mu_\tau, \sigma_\tau, \rho, \tau_e\}$, a stationary equilibrium is an invariant size distribution $g(s)$, value and policy functions of incumbent establishments $W(s)$, $k(s)$, $n(s)$, establishment productivity growth $\mu_z$, value of entrants $W_e$, entrants' productivity $z_e$, entry rate $b$, prices $(r, w)$, transfer $T$, profits $\Pi$, capital $K$, and consumption $C$, such that:

 i) Consumer optimization implies that $R = r - \delta_k = \varrho$ and aggregates $C$ and $K$.

 ii) Given prices, the incumbents' policy functions $\{k(s), n(s)\}$ solve the incumbents' static problem (2).

 iii) Given prices, the incumbents' value function $W(s)$ solves the incumbents' dynamic problem (6), $\mu_z$ is optimal from this problem.

 iv) Given prices, the value of entrants satisfy the zero profit condition in (9) and entry productivity $z_e$ is determined by this condition.

 v) The stationary distribution $g(s)$ and entry rate of establishments $b$ solve the Kolmogorov-Fokker-Planck equation (11).

 vi) Markets for capital and labor clear (market clearing in the goods market is satisfied by Walras' law):

a) capital: $K = \int_0^{+\infty} k(s)g(s)ds,$

b) labor: $1 = \int_0^{+\infty} n(s)g(s)ds.$

vii) Transfers $T$ guarantee that the government's budget constraint is satisfied.

# 4 Aggregate Output and Productivity

Aggregate output $Y$ is obtained by integrating over the distribution of establishment's output. From the establishment production function in equation (1), we substitute the demand for labor and capital in equations (3) and (4), and use the labor market clearing condition to substitute for the wage to obtain:

$$y(z, \tau) = \left(\frac{\alpha}{r}\right)^{\frac{\alpha}{1-\alpha}} \left(\frac{1}{\bar{s}}\right)^{\frac{\gamma}{1-\alpha}} \tau^{\theta(\alpha+\gamma)} z^{\theta}. \tag{17}$$

Given that $y \propto \tau^{\theta(\alpha+\gamma)} z^{\theta}$ is a Brownian motion, the output drift is equal to

$$\mu_y = \mu_{\tau^{\theta(\alpha+\gamma)} z^{\theta}} = \theta \mu_z + \theta(\theta-1)\sigma_z^2/2 + (\alpha+\gamma)\left\{\theta\mu_\tau + \theta^2 \rho \sigma_z \sigma_\tau + \left[\theta^2(\alpha+\gamma) - \theta\right]\sigma_\tau^2/2\right\}.$$

After integrating, using the same methodology as in Lemma 2, and rearranging terms we write aggregate output $Y$ and total factor productivity $Y/K^{\alpha}$ as:[4]

$$
\begin{aligned}
Y &= \left(\frac{\alpha}{r}\right)^{\frac{\alpha}{1-\alpha}} \left(\frac{\lambda - \mu_s}{\lambda - \mu_y}\right) \bar{s}^{\frac{1-\alpha-\gamma}{1-\alpha}} \left(\frac{1}{\tau_e^{\theta(1-\alpha-\gamma)}}\right), \\
\text{TFP} &= \left(\frac{\lambda - \mu_s}{\lambda - \mu_y}\right) \bar{s}^{1-\alpha-\gamma} \left(\frac{1}{\tau_e^{\theta(1-\alpha-\gamma)}}\right).
\end{aligned}
$$

These equations highlight the relevance of the wedge between the output and size drifts in distorted

---

[4]Aggregate capital is given by integrating equation (4) over size,

$$K = \left(\frac{\alpha}{r}\right)^{\frac{1}{1-\alpha}} \bar{s}^{\frac{1-\alpha-\gamma}{1-\alpha}} = \left(\frac{\alpha}{r}\right)^{\frac{1}{1-\alpha}} \left[\left(\frac{\lambda}{\lambda - \mu_s}\right)\left(\tau_e^{\theta} z_e^{\theta}\right)\right]^{\frac{1-\alpha-\gamma}{1-\alpha}}.$$

economies. In particular, note that in this framework aggregate output and productivity may be lower with policy distortions not only through their effects on average establishment size $\bar{s}$, but also by the wedge between size and output drifts. Recall that these drifts determine the average size and output relative to entry and their underlined distributions. It turns out that this feature of the environment is critical in understanding the quantitative effects of policy distortions relative to the literature with endogenous establishment productivity as we discuss below.

**Model solution.** We can easily solve for the stationary equilibrium. First, the stationary rental rate of capital $r$ is pin down by $\varrho$ and $\delta_k$ from the household problem in steady state. Second, we solve a non-linear system of five equations in five unknowns $\{z_e, \mu_z, \mu_s, \bar{s}, A\}$ as follows:

(1) The free entry condition:
$$A(\tau_e z_e)^\theta = c_e. \tag{18}$$

(2) The productivity growth rate $\mu_z$:
$$\mu_z = \left[ \frac{\theta A \bar{s}}{c_\mu} \right]^{\frac{1}{\theta - 1}}. \tag{19}$$

(3) The size growth rate,
$$\mu_s = \theta \mu_z + \theta(\theta - 1)\sigma_z^2/2 + \theta \mu_\tau + \theta(\theta - 1)\sigma_\tau^2/2 + \theta^2 \rho \sigma_z \sigma_\tau. \tag{20}$$

(4) The relative incumbent to entry size:
$$\frac{\bar{s}}{(\tau_e z_e)^\theta} = \left( \frac{\lambda}{\lambda - \mu_s} \right), \tag{21}$$

which given the labor market clearing condition implies the wage rate $w = \gamma \left( \frac{\alpha}{r} \right)^{\frac{\alpha}{1-\alpha}} \bar{s}^{\frac{1-\alpha-\gamma}{1-\alpha}}$.

(5) The establishment's value to size ratio $A$ is:

$$A = \frac{(1 - \alpha - \gamma)}{(\lambda + R + \mu_z - \mu_s)} \left(\frac{\alpha}{r}\right)^{\frac{\alpha}{(1-\alpha)}} \left(\frac{1}{\bar{s}}\right)^{\frac{\gamma}{1-\alpha}}. \tag{22}$$

Note that this system has a closed-form solution. From the free entry condition in equation (18), we substitute $A$ in equation (19) and use the relative incumbent to entry size condition in equation (21) to substitute for $\bar{s}/(\tau_e z_e)^\theta$ and obtain the equilibrium condition between productivity and size growth rates:

$$\mu_z = \left[\frac{\theta c_e}{c_\mu}\left(\frac{\lambda}{\lambda - \mu_s}\right)\right]^{\frac{1}{\theta - 1}}. \tag{23}$$

Using $\mu_s$ from equation (20), we obtain the solution for the productivity growth rate:

$$\theta\mu_z^\theta - \mu_z^{\theta-1}\left[\lambda - \theta(\theta - 1)\sigma_z^2/2 - \theta\mu_\tau - \theta(\theta - 1)\sigma_\tau^2/2 - \theta^2\rho\sigma_z\sigma_\tau\right] + \lambda\theta\frac{c_e}{c_\mu} = 0. \tag{24}$$

Given the solution for $\mu_z$ we can solve sequentially for all the other equilibrium variables as follows:

$$\mu_s = \theta\mu_z + \theta(\theta - 1)\sigma_z^2/2 + \theta\mu_\tau + \theta(\theta - 1)\sigma_\tau^2/2 + \theta^2\rho\sigma_z\sigma_\tau \tag{25}$$

$$\bar{s}^{\frac{1-\alpha-\gamma}{1-\alpha}} = \left(\frac{\lambda c_e}{\bar{m}(r)}\right)\left[\frac{\lambda + R - \mu_s + \mu_z}{\lambda - \mu_s}\right], \tag{26}$$

$$s_e = \left(1 - \frac{\mu_s}{\lambda}\right)\bar{s}, \tag{27}$$

$$z_e = s_e^{1/\theta}/\tau_e. \tag{28}$$

**Restricting the (relative) size distribution.** Following Axtell (2001) and Gabaix (2009), we characterize analytically the impact of distortions on the productivity drift by focusing on economies satisfying Zipf's law (for a more general discussion of power laws in economics, see Gabaix, 2016). Recall that the distribution of relative sizes (equation 15), satisfies the characteristic equation (16).

Using equations (8) and (10), we rewrite the characteristic equation as:

$$\lambda = \theta\xi \left\{ \mu_z + \mu_\tau + (\xi\theta - 1)(\sigma_z^2 + \sigma_\tau^2)/2 + \theta\xi\rho\sigma_z\sigma_\tau \right\}. \tag{29}$$

Given $\mu_z$ in equation (24), we use equation (29) to substitute for $\lambda$, and taking the limit $\xi \to 1$ (Zipf's law) we have $\theta\dfrac{c_e}{c_\mu} = 0 \Rightarrow \lambda = 0$. That is Zipf's law implies $\lambda \to 0$ and the associated productivity drift is given by:

$$\mu_z = -[\mu_\tau + (\theta - 1)\sigma_\tau^2/2] - [\theta\rho\sigma_\tau\sigma_z + (\theta - 1)\sigma_z^2/2].$$

We use this expression to derive the change in the productivity drift $\mu_z$ from changes in distortions $(\sigma_\tau, \rho)$:

$$\frac{d\mu_z}{d\sigma_\tau} = -[(\theta - 1)\sigma_\tau + \theta\rho\sigma_z], \tag{30}$$

which implies that productivity growth is lower with higher distortions (higher $\sigma_\tau$) and with higher negative correlation ($\rho$). Note that with negative correlation, dispersion in $\tau$ and $z$ have opposite effects on the productivity growth rate. Another important implication of this result is that with $\rho = -1$ as in the existing literature (e.g., Hsieh and Klenow, 2014; Bento and Restuccia, 2017; Buera and Fattal Jaef, 2018), the impact of distortions on productivity growth is a lower bound.

What is the actual impact of stochastic growth on aggregate productivity in this framework? We answer this question in the next section using a stylized numerical quantification.

# 5    Quantitative analysis

We assess the quantitative impact of policy distortions on aggregate output and productivity. The key discipline in the numerical explorations below is that we focus on economies with identical size

distributions which approximate Zipf's law (Axtell, 2001; Gabaix, 2009; Hopenhayn, 2014b).

**Calibration.** We calibrate a benchmark economy with distortions and then study the impact of alternative hypothetical policy distortions in the same spirit of Restuccia and Rogerson (2008).

We start by selecting a set of parameters that are standard in the literature. These parameters have either well-known targets, which we match, or the values have been well discussed in the literature. Following the literature, we assume decreasing returns in the establishment-level production function and set $\alpha + \gamma = 0.85$ (Restuccia and Rogerson, 2008). Then we split it between $\alpha$ and $\gamma$ by assigning $1/3$ to capital and $2/3$ to labor, implying $\alpha = 0.283$ and $\gamma = 0.567$. We set the discount rate $\varrho$ to match a real interest rate of 4 percent and the depreciation rate of capital $\delta$ to 7 percent to match a capital to output ratio of 2.5. We normalize $\tau_e = 1$ ($\tau_{y,e} = 0$) and keep it constant across all economies. For the benchmark economy we set $\rho = -0.09$ based on the near zero elasticity between distortions and productivity in U.S. manufacturing (Hsieh and Klenow, 2009, 2014).

We then solve the stationary equilibrium and select the following 6 parameters to match 6 moments from the data. We select $c_\mu$ to match an establishment productivity growth rate of 4% ($\mu_z = 0.04$); $\theta$ to match an establishment output growth rate of 5% ($\mu_y = 0.05$); $\sigma_z^2$ and $\lambda$ are selected to match an exit rate of 10% in line with estimates in the literature (Davis et al., 1998) and the positive root of the size distribution of 1.056 from Axtell (2001) ($\xi_+ = 1.056$); $\sigma_\tau^2$ to match the standard deviation of the log of TFPR (see Appendix A.3) of 0.49 (Hsieh and Klenow, 2009); $\mu_\tau$ to normalize mean distortions to 1 (mean $\tau^\theta = 1$); and $c_e$ to match an average establishment size $\bar{s} = 21.85$ (Hsieh and Klenow, 2009). Parameter values and moments are summarized in Table 1.

**Experiments.** We study the impact of policy distortions on establishment-level productivity, aggregate output and TFP, and other relevant variables by comparing statistics in more distorted economies than the benchmark economy.

We first highlight the impact of policy distortions in our model with effects on establishment-level productivity relative to a version of the model where $\xi_s$ is not constant across economies.

Table 1: Calibration Benchmark Economy

| Parameter | Value | Target | Value |
|---|---|---|---|
| $c_\mu$ | 95.06 | establishment productivity growth rate | 0.04 |
| $\theta$ | 1.80 | establishment output growth rate | 0.05 |
| $\sigma_z^2$ | 0.0390 | Exit rate | 0.10 |
| $\lambda$ | 0.10 | Positive root size distribution ($\xi_+$) | 1.056 |
| $\sigma_\tau^2$ | 0.1492 | SD log TFPR | 0.49 |
| $\mu_\tau$ | -0.0597 | Normalized, mean $\tau^\theta$ | 1.00 |
| $c_e$ | 0.8937 | Average size ($\bar{s}$) | 21.85 |

We study the impact of changes in policy distortions by considering economies that are relatively more distorted than the benchmark economy via changes in the dispersion of distortions $\sigma_\tau$. Specifically, we increase $\sigma_\tau^2$ while holding constant mean distortions and the size distribution $\xi_s$.[5] We consider variations in $\sigma_\tau$ within the range of estimates in the empirical literature (Hsieh and Klenow, 2009; Buera et al., 2013; Bento and Restuccia, 2017; Cirera et al., 2017; Restuccia and Rogerson, 2017). We emphasize that while we have witnessed a tremendous increase in firm-level data availability around the world, access to firm-level data and comparisons of samples across countries remain a challenge. For this reason, we find it useful to consider hypothetical economies to study the dynamic effects of misallocation. These experiments are not meant to represent any individual country but instead provide an assessment of the role of distortions on establishment-level productivity and aggregate output in our model relative to the existing literature.

We document our quantitative results in Figure 1 by reporting equilibrium values of the productivity drift $\mu_z$, average size $\bar{s}$, entry size $s_e$, aggregate TFP, power laws relating to the distribution of distortions, TFP, and size; among other relevant statistics.

Figure 1, red-dashed line, shows that in economies with low correlated distortions ($\rho = -0.09$) an increase in policy distortions increases $\mu_z$ and generate a more unequal establishment distribution (lower $\xi_s$ than in the benchmark economy). These effects arise from the fact that with correlated distortions, $\rho < 0$, an increase in policy distortions decreases stochastic growth, $\text{cov}(z^\theta, \tau^\theta) =$

---
[5]Noe that mean $\tau^\theta = 1$ implies that $\theta\mu_\tau + \theta(\theta - 1)\sigma_\tau^2/2 = 0$.

## Figure 1: Policy Distortions $\sigma_\tau^2$ and Zipf's Law

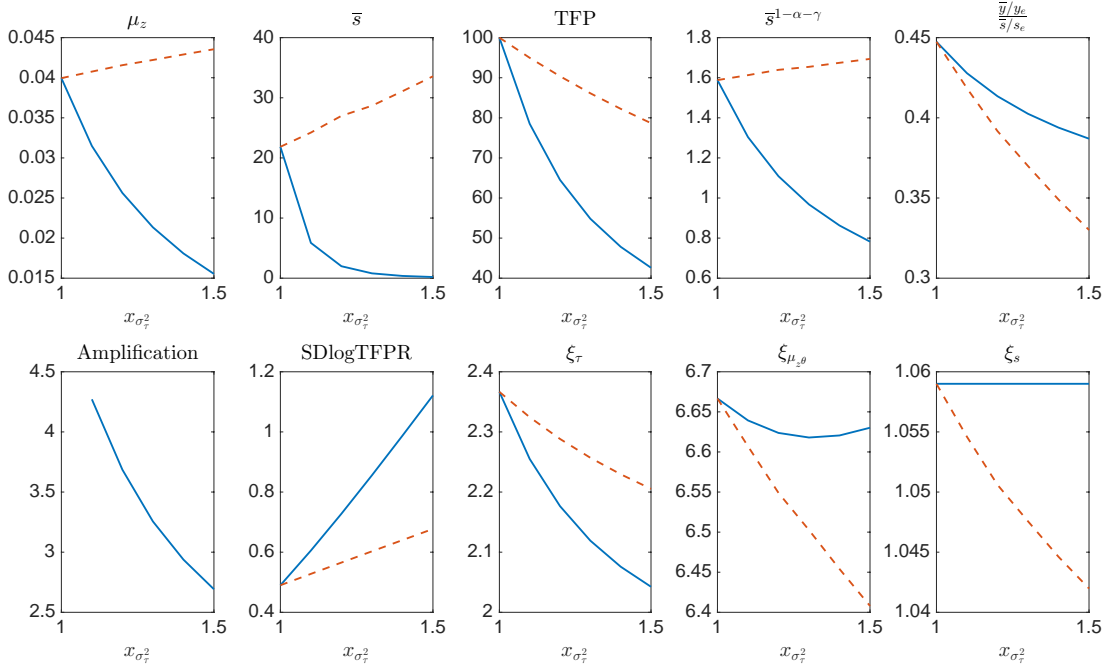

Notes: The blue-solid line represents the benchmark economy with changes in $\sigma_\tau^2$ with constant $\xi_s$. The red-dashed line represents the same economies without restricting $\xi_s$. In all economies, $\mu_\tau$ is adjusted to normalize mean distortions to one, i.e., mean $\tau^\theta = 1$.

$\rho\theta^2\sigma_z\sigma_\tau$, and reduce (all other things equal) size growth $\mu_s = \mu_{z^\theta} + \text{cov}(z^\theta, \tau^\theta)$. Establishments react by investing in productivity.[6] And when $\rho \to 0$, the endogenous investment effect on productivity dominates the stochastic effect (note that when $\rho \to -1$ the opposite holds). Therefore, an increase in policy distortions increases $\mu_s$ and generates a more unequal establishment size distribution (lower $s_e/\bar{s}$).

However, if Zipf's law holds (the size distribution is constant), blue-solid line in Figure 1, the establishment size inequality (measured by $\xi_s$) bounds the inequality in the establishment productivity distribution. The same (relative) establishment size distribution is compatible with a more unequal establishment productivity distribution if the establishment expects a higher lifespan (lower $\lambda$) that increases the desincentive to invest in productivity generated by the distortion. The effect of policy

---

[6]Note that $\theta\mu_z^\theta - \mu_z^{\theta-1}\left[\lambda - \theta(\theta-1)\sigma_z^2/2 - \text{cov}(z^\theta, \tau^\theta)\right] + \lambda\theta\dfrac{c_e}{c_\mu} = 0$. Given that $\mu_z > 0$ and $\dfrac{d\mu_z}{dc_{\mu_z}} < 0$, we have that $\dfrac{d\mu_z}{d\text{cov}(z^\theta, \tau^\theta)} > 0$.

distortions on aggregate productivity is substantial when Zipf's law holds, a reduction of 57 percent compared with only 21 percent with changes in the size distribution (a 2.8-fold larger impact).

Figure 2 reports the change in aggregate output in our framework (blue-solid line) relative to the model with $\rho = -1$ (red-dashed line) as in the existing literature. Note that in economies where $\rho \to -1$ the impact of misallocation on stochastic growth reaches its maximum (negative) value, whereby we expect a negative impact of policy distortions on $\mu_s$.

Figure 2: The Role of Correlation ($\rho = -1$)
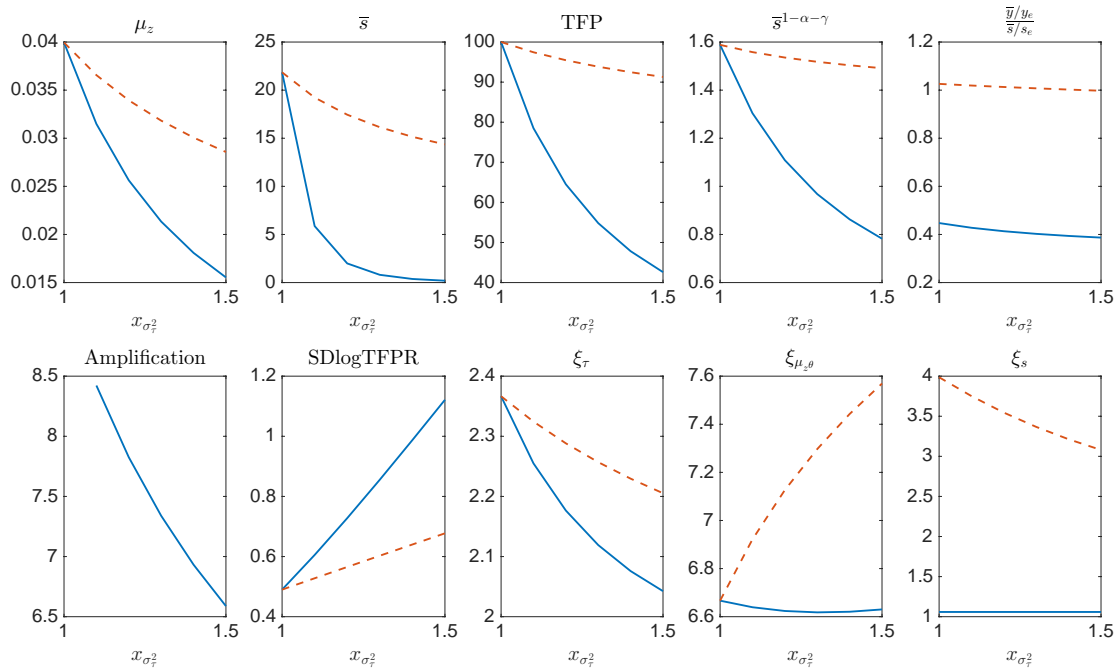

Notes: The blue-solid line represents the benchmark economy with changes in $\sigma_\tau^2$ with constant $\xi_s$. The red-dashed line represents alternative economies with $\rho = -1$ and without restricting $\xi_s$. In all economies, $\mu_\tau$ is adjusted to normalize mean distortions to one, i.e., mean $\tau^\theta = 1$.

Consistent with the literature, an increase in policy distortions decreases productivity growth, average size, entry productivity, and aggregate TFP. The decline in aggregate TFP is substantial, of more than 57 percent, especially when compared to the case when $\rho = -1$ where the decline in TFP is around 9 percent (a 6.9-fold larger impact). These results arise with only modest increases in the dispersion in revenue productivity, well within the ranges reported in the literature.

If the distribution of relative sizes can differ across economies, our model (equations 24-28) indicates that changes in $\sigma_\tau^2$ affect size if distortions are correlated ($\rho < 0$). If instead $\rho = 0$, changes in $\sigma_\tau^2$ leave $\mu_z$, $\mu_s$, $\bar{s}$, and $K$ constant and changes in aggregate TFP are due to changes in $Y$,

$$TFP \propto Y \propto \frac{1}{\lambda - \mu_y},$$

where $\mu_y = \mu_{z^\theta} + (\alpha + \gamma)(1 - \alpha - \gamma)\sigma_{\tau^\theta}^2/2$. As a result, the literature has emphasized the role of correlated distortions. Assuming that $\tau = z^{-\nu}$ is equivalent in our model to assuming that $\rho = -1$ where the dispersion in distortion is affected by changes in $\nu$ ($\sigma_\tau^2 = \nu^2\sigma_z^2$).

What happens if we assume, in addition, that the distribution of (relative) establishment sizes is invariant across economies? Absent distortions, our model interprets the empirical phenomenon of Zipf's law as in Luttmer (2007). Zipf's law is the result of high entry costs $c_e$, low R&D investment $c_{\mu_z}$ (which in our model plays the oposite role of the cost of imitation in Luttmer, 2007), or both. But in distorted economies, our model offers another possible interpretation of Zipf's law as the result of combinations of high dispersion of (relative) sizes $\sigma_x^2 = \sigma_{z^\theta}^2 + \sigma_{\tau^\theta}^2 + 2 \ \text{cov}(z^\theta, \tau^\theta)$ and high establishments' lifespan (low $\lambda$'s), to induce lower $\mu_z$ and $\mu_s$. Under this interpretation, it is straightforward to see why holding the distribution of sizes across economies is key for the quantitative assessment of policy distortions on aggregate outcomes.

More misallocation implies that the dispersion of establishment sizes $\sigma_x^2$ is higher. Keeping $\xi_s$ constant across economies implies that more distorted economies feature lower $\lambda$'s, which amplifies the effect of distortions $\sigma_\tau^2$ on productivity growth $\mu_z$.

# 6 Conclusions

We develop a tractable dynamic model of heterogeneous producers to study the effect of distortions on the distribution of establishment-level productivity across economies. The model tractability allows us to obtain closed-form solutions that are useful in identifying the response of distortions on

aggregate output. We show that policy distortions have substantial negative effects on aggregate output and TFP in this economy compared to the existing literature.

It would be interesting to explore specific policies and institutions—such as size-dependent policies, firing taxes, financial frictions—in the context of our framework with dynamic effects of distortions (see for example, Da-Rocha et al., 2019; Aghion et al., 2021). These explorations of specific policies in our framework may help reconcile the empirically large effects found in the literature. As a result, further progress aimed at broadening the empirical mapping of the model to the data may provide useful insights. Our analytical solution of the productivity distribution as a function of distortions is a critical first step in this mapping. But the mapping requires reliable and comparable panel data of producers across countries. While these data are increasingly available for some countries, comparability across countries remains an important limitation. We leave these interesting and important explorations for future work.

# A  Appendix

This appendix presents the proofs of Lemma 1 and Lemma 2, the detailed steps to calculate aggregate output, and the characterization of the distribution of TFPR.

## A.1  Proof Lemma 1

From the first order condition for the productivity drift in equation (7), we can solve for the productivity drift $\mu_z$ as a function of the determinants of costs and benefits such as distortions $\tau$, cost scale $c_\mu$, and the marginal present value profits $W'_z$. In particular, equating the marginal cost and benefit from productivity growth implies,

$$\frac{c_\mu}{\bar{s}}(z\tau)^\theta \mu_z^{\theta-1} = zW'_z.$$

By guessing and verifying, we find that the optimal Hamilton-Jacobi-Bellman equation is given by $W(z,\tau) = A(w,r)z^\theta\tau^\theta$, where the constant $A(w,r)$ is the solution of the polynomial:

$$\left[\frac{(\lambda+R)}{(\theta-1)} - \frac{\theta\mu_\tau}{(\theta-1)} - \frac{\theta^2\sigma_z\sigma_\tau\rho}{(\theta-1)} - \frac{\theta(\sigma_z^2+\sigma_\tau^2)}{2}\right]A(w,r)$$

$$-\left[\frac{\theta\bar{s}}{c_\mu}\right]^{\frac{1}{\theta-1}}A(w,r)^{\frac{\theta}{\theta-1}} = \frac{m(w,r)}{(\theta-1)}.$$

After this simplification, we rewrite equation (A.1) finding the following expression for $A(w,r)$:

$$A(w,r) = \frac{m(w,r)}{\lambda + R - \theta\mu_\tau - \theta^2\sigma_z\sigma_\tau\rho - \dfrac{\theta(\theta-1)}{2}(\sigma_z^2+\sigma_\tau^2) - (\theta-1)\mu_z}, \tag{A.1}$$

where $\mu_z$ depends on $A(w,r)$. Given the solution to this polynomial, the optimal productivity drift $\mu_z$ is independent of establishment characteristics $\tau$ and $z$:

$$\mu_z = \left[\frac{\theta A(w,r)\bar{s}}{c_\mu}\right]^{\frac{1}{\theta-1}}.$$

## A.2  Proof Lemma 2

After some algebraic manipulation from equation (12), we find that the stationary distribution must satisfy the following differential equation:

$$f''(x) - \frac{2\mu_x}{\sigma_x^2} f'(x) - \frac{2\lambda}{\sigma_x^2} f(x) = -\frac{2b}{\sigma_x^2} \delta(x - 0),$$

subject to the boundary conditions and $f(\cdot)$ being a pdf. Therefore, the stationary pdf is the solution of the boundary-value problem that consists of solving

$$f''(x) - \gamma_1 f'(x) - \gamma_2 f(x) = 0 \qquad \text{if} \quad x \neq 0,$$
$$f''(x) - \gamma_1 f'(x) - \gamma_2 f(x) = -\gamma_3 \delta(x - 0) \quad \text{if} \quad x = 0,$$

where the constants $\gamma_1$, $\gamma_2$, and $\gamma_3$ are given by

$$\gamma_1 = \frac{2\mu_x}{\sigma_x^2} < 0, \quad \gamma_2 = \frac{2\lambda}{\sigma_x^2} > 0, \quad \gamma_3 = \frac{2\hat{b}}{\sigma_x^2} > 0.$$

We solve the boundary-value problem using Laplace transforms. Laplace transforms are given by

$$\mathscr{L}[f'(x)] = s\mathscr{L}[f(x)] - f(0),$$
$$\mathscr{L}[f''(x)] = s^2 \mathscr{L}[f(x)] - sf(0) - f'(0).$$

By applying Laplace transforms in equation (12), we obtain:

$$(s^2 - \gamma_1 s - \gamma_2)\mathscr{L}[f(x)] - (s - \gamma_1)f(0) - f'(0) = -\gamma_3 \mathscr{L}[\delta(x - 0)].$$

Using the boundary condition $f(0) \geq 0$ and $\mathscr{L}[\delta(x - 0)] = 1$ we find:

$$(s^2 - \gamma_1 s - \gamma_2)Y(s) = f'(0) + (s - \gamma_1)f(0) - \gamma_3,$$

where

$$Y(s) = \frac{f'(0) - \gamma_3 + (s - \gamma_1)f(0)}{(s^2 - \gamma_1 s - \gamma_2)}.$$

We obtain the solution by solving the Laplace inverses when $x \neq 0$ given by:

$$\mathscr{L}^{-1}\left[\frac{1}{(s - r_1)(s - r_2)}\right] = \frac{1}{(r_1 - r_2)}\left(e^{r_1 x} - e^{r_2 x}\right),$$

$$\mathscr{L}^{-1}\left[\frac{(s - \gamma_1)}{(s - r_1)(s - r_2)}\right] = \frac{1}{(r_1 - r_2)}\left[(r_1 - \gamma_1)e^{r_1 x} - (r_2 - \gamma_1)e^{r_2 x}\right],$$

where the two roots (one positive and one negative) are given by $r = \dfrac{\gamma_1 \pm \sqrt{\gamma_1^2 + 4\gamma_2}}{2}$. We can rewrite the final solution for this case as:

$$f(x) = \frac{f'(0)}{(r_1 - r_2)}\left(e^{r_1 x} - e^{r_2 x}\right) + \frac{f(0)}{(r_1 - r_2)}\left[(r_1 - \gamma_1)e^{r_1 x} - (r_2 - \gamma_1)e^{r_2 x}\right] \quad \text{if} \quad x \neq 0,$$

$$f(x) = \frac{f'(0) - \gamma_3}{(r_1 - r_2)}\left(e^{r_1 x} - e^{r_2 x}\right) + \frac{f(0)}{(r_1 - r_2)}\left[(r_1 - \gamma_1)e^{r_1 x} - (r_2 - \gamma_1)e^{r_2 x}\right] \quad \text{if} \quad x = 0.$$

When $x \neq 0$ (that is $\forall x \in (-\infty, 0) \cup (0, \infty)$), we have

$$f(x) = \begin{cases} C_1 e^{r_1 x} + C_2 e^{r_2 x}, & \text{if} \quad x < 0, \\ \\ C_1 e^{r_1 x} + C_2 e^{r_2 x}, & \text{if} \quad x > 0, \end{cases}$$

where

$$C_1 = \frac{1}{(r_1 - r_2)}\left[f'(0) + f(0)(r_1 - \gamma_1)\right],$$

$$C_2 = \frac{-1}{(r_1 - r_2)}\left[f'(0) + f(0)(r_2 - \gamma_1)\right],$$

and $r_1 > 0$ and $r_2 < 0$. When $x > 0$ in order to $f(\cdot)$ be a pdf, it is necessary that $C_1 = 0$ and

$$f'(0) = -f(0)(r_1 - \gamma_1) \Rightarrow C_2 = \frac{-1}{(r_1 - r_2)}\left[f(0)(\gamma_1 - r_1) + f(0)(r_2 - \gamma_1)\right] = f(0).$$

Symmetrically when $x < 0$ we need $C_2 = 0$. Therefore,

$$f'(0) = -f(0)(r_2 - \gamma_1) \Rightarrow C_1 = \frac{1}{(r_1 - r_2)}[f(0)(\gamma_1 - r_2) + f(0)(r_1 - \gamma_1)] = f(0),$$

and

$$f(x) = \begin{cases} f(0)e^{r_1 x} & \text{if } x < 0, \\ \\ f(0)e^{r_2 x} & \text{if } x \geq 0, \end{cases}$$

where $f(0) = \left(\frac{r_1 r_2}{r_2 - r_1}\right)$. Finally we need to prove that: 1) for $x > 0$, $f'(0) = -f(0)(r_1 - \gamma_1)$ (i.e. $C_1 = 0$), and 2) for $x < 0$, $f'(0) = -f(0)(r_2 - \gamma_1)$ (i.e. $C_2 = 0$); Given that when $x > 0$ $f'(0) = r_2 f(0)$ (and when $x < 0$ $f'(0) = r_1 f(0)$) this is equivalent to show that

$$(r_2 + r_1)f(0) = \left(\frac{\gamma_1 - \sqrt{\gamma_1^2 + 4\gamma_2}}{2} + \frac{\gamma_1 + \sqrt{\gamma_1^2 + 4\gamma_2}}{2}\right)f(0) = f(0)\gamma_1.$$

When $x = 0$ we have

$$f(x) = C_1 e^{r_1 x} + C_2 e^{r_2 x},$$

where

$$\begin{aligned} C_1 &= \frac{1}{(r_1 - r_2)}[f'(0) - \gamma_3 + f(0)(r_1 - \gamma_1)], \\ C_2 &= \frac{-1}{(r_1 - r_2)}[f'(0) - \gamma_3 + f(0)(r_2 - \gamma_1)]. \end{aligned}$$

Therefore

$$f(0) = C_1 + C_2 = \frac{1}{(r_1 - r_2)}[r_1 f(0) - r_2 f(0)] = f(0).$$

Using $s = s_e e^x$, we can recover the size distribution $g(s)$. That is

$$g(s) = \frac{1}{s} f(\ln(s/s_e)) = \begin{cases} f(0) \dfrac{s^{r_1-1}}{s_e^{r_1}} & \text{if} \quad s < s_e, \\[2em] f(0) \dfrac{s^{r_2-1}}{s_e^{r_2}} & \text{if} \quad s \geq s_e. \end{cases}$$

Note that this solution is equivalent to the guess and verify solution obtained by solving the characteristic equation $\dfrac{\sigma_x^2}{2}\xi^2 + \left(\mu_s - \dfrac{\sigma_x^2}{2}\right)\xi - \lambda = 0$ with $r_1 = -\xi_-$ and $r_2 = -\xi_+$.

Finally, average establishment size $\bar{s}$ is given by

$$\bar{s} = s_e \frac{-\xi_-\xi_+}{(\xi_+ - 1)(1 - \xi_-)} = s_e \left(\frac{\lambda}{\lambda - \mu_s}\right).\blacksquare$$

## A.3 TFPR

In our model, an establishment's TFPR is given by:

$$\text{TFPR} \quad = \quad \frac{y}{k^{\alpha/(\alpha+\gamma)}n^{\gamma/(\alpha+\gamma)}} \propto \frac{1}{\tau^{\theta(1-\alpha-\gamma)}} = \frac{1}{(1-\tau_y)},$$

which is equated across all establishments in the undistorted economy. In this context, misallocation arises from dispersion in TFPR across establishments. In our environment, the distribution of distortions $g_\tau(\tau)$ is a Double Pareto. Therefore, log TFPR follows a Double Exponential with roots $\xi_{TFPR,-}$ and $\xi_{TFPR,+}$ that solve the characteristic equation:

$$\frac{\sigma_{TFPR}^2}{2}\xi^2 + \left(\mu_{TFPR} - \frac{\sigma_{TFPR}^2}{2}\right)\xi - \lambda = 0,$$

where $\mu_{TFPR} = -\theta(1-\alpha-\gamma)\mu_\tau - \theta(1-\alpha-\gamma)(-\theta(1-\alpha-\gamma)-1)\frac{\sigma_\tau^2}{2}$ and $\sigma_{TFPR}^2 = \theta^2(1-\alpha-\gamma)^2\sigma_\tau^2$. Standard deviation of log revenue total factor productivity (TFPR):

$$\text{SD log TFPR} = \sqrt{\frac{1}{\xi_{TFPR,-}^2} + \frac{1}{\xi_{TFPR,+}^2}}.$$
